Separation P rocesses in the P resence of Cycl odextrins Using Molecular Imprinting Technology and Ionic Liquid Cooperating Approach

Jingjing Zhang, Xinghai Shen* and Qingde Chen

Beijing National Laboratory for Molecular Sciences (BNLMS), Department of Applied Chemistry, College of Chemistry and Molecular Engineering, Peking University, Beijing 100871, China

Abstract: Recently, separation science in the presence of cyclodextrins (CDs) has been paid more and more attention. Two important technologies based on CDs, molecularly imprinted polymers (MIPs) and ionic liquid (IL) cooperating approach, have been studied extensively and not been reviewed. MIPs are significant and important in separation processes. MIPs based on cyclodextrins (CD-MIPs) take advantage of unique properties of cyclodextrins and are applied in the separation of various molecules. Different methods for preparation CD-MIPs and supramolecular interactions in the systems are reviewed. Furthermore, ILs have been also widely used in separation science. Cooperative effect of CDs and ILs together for separation usage is discussed in this paper. The related separation techniques are mainly capillary electrophoresis (CE) and gas chromatography (GC). CD-MIPs and cooperative effect of ILs in separation methods, which are two important aspects in cyclodextrins separation science, are summarized here. It is hoped that the discussion on the above two topics will stimulate further research.

Keywords: Cyclodextrin(s), separation, molecularly imprinted polymer(s), ionic liquid(s).

1. INTRODUCTION

Supramolecular chemistry is intriguing and potential for future functional molecular devices, nanoscience and so on [1]. Cyclodextrins (CDs), one of the most important host molecules in supramolecular chemistry, are ideally suitable to accommodate various kinds of guest molecules into their cavities [2-9]. Due to "Host-Guest" interactions, CDs have been studied extensively in separation processes [10-14]. There are many separation technologies based on CDs and they have been reviewed distinctly [15-22]. Two important separation technologies based on CDs, one is molecular imprinting technology, the other is ionic liquid (IL) cooperating approach [23-25], have been paid much attention, however, there is no review so far. As a result, the two significant aspects of CDs applied in separation will be the main focus of the present review.

Recently, there are more and more reports on the molecularly imprinted polymers (MIPs) because of their high efficiency, good selectivity, reusability, low cost and so on [26-32]. Compared with conventional MIPs, molecularly imprinted polymers based on cyclodextrin (CD-MIPs) not only reserve the binding sites of polymers, but also possess some unique advantages for separation. Firstly, the host-guest inclusion complex of CD and the orderly assembly of CD polymer are easily formed under mild conditions. Secondly, due to the rigidity and chirality of hydrophobic cavity, CD unit can form complex with the target analyte through various kinds of intermolecular interactions (Van der Waals force, hydrophobic interaction, electrostatic affinity, dipole-dipole interaction, and hydrogen bonding) during the imprinting process, which is helpful to obtain high affinity binding sites. Thirdly, owing to the fast and reversible interaction between CDs and guest, the prepared CD-MIPs can be easily regenerated by suitable regulation and control. Therefore, this review will summarize the works on CD-MIPs. We will demonstrate different methods of preparing MIPs and emphasize on the interaction in the systems.

ILs, a kind of organic salts, are liquids at or near room temperature. They have been widely used in many fields because of their negligible vapor pressure, nonflammability, high thermal and chemical stability, high polarity, wide electrochemical window and tunable physical-chemical properties. They can also be designed to be environmentally benign, with large potential benefit for sustainable chemistry [33-41]. Among their various applications, separation is important and intriguing [42-45]. Owing to the interaction of ILs with CDs, separation processes of CDs and ILs together may demonstrate interesting phenomena. Factually, the problem has been considered and CDs cooperated with ILs have been applied in separation methods. The interaction of CDs, ILs and analytes has been taken into consideration. Here, we will overview the works on the topic and emphasize on the interaction of CDs, ILs and analytes.

2. M OLECULARLY I MPRINTED POLYM ERS BASED ON CYCLODEXTRINS

Molecular imprinting technology (MIT), which is pioneered by Wulff [46] and Mosbach [47], aims to mimic the high selectivity of molecular recognition. The process of molecular imprinting involves the formation of recognition cavities through connecting of the different building blocks under the guidance of a molecular template. MIT has been studied extensively and potential applications of molecularly imprinted materials have been discussed in several review papers [48-54]. CD-MIPs have been examined for sensing of organic compounds and efficient recognition of steroids, peptides, amino acids and their derivatives, antibiotics, *etc.* [55-61] There are mainly two methods of preparing CD-MIPs, *i.e.* bulk imprinting and surface imprinting.

2.1. Bulk Imprinting

For bulk imprinting, the process of MIPs preparation proceeds in solution and there is no solid support for imprinting. Most of CD-MIPs are obtained by this method and they are used to recognize both small and large guests [62,63].

As reported by Breslow *et al.*, cyclodextrin dimer and trimer can recognize efficiently steroids, peptides, and other biologically

Fig. (1). Reagents and conditions of preparing MIP based on β -CD for recognition of cholesterol: i, hexane–H₂O; ii, diisocyanate in DMSO; iii, acetone, H₂O, THF, EtOH. Taken from Ref. [55].

important molecules [64]. MIP based on β -cyclodextrin (β -CD-MIP) (Fig. (1)) has been prepared for efficient recognition of cholesterol in dimethyl sulfoxide (DMSO) [55,56]. The crosslinking agents used are hexamethylene diisocyanate (HMDI) and toluene 2,4-diisocyanate (TDI). However, the imprinted polymer with TDI demonstrates greater absorbing ability to cholesterol than that with HMDI. It suggests that the molecular rigidity of TDI is more adequate to regulate the positions of the β -cyclodextrin (β -CD) residues strictly.

Tailor-made receptors for hydrophobic guest molecules are realized by imprinting of CDs (Fig. (2)) [65]. Among the templates of MIPs, those having rigid molecular structures are effectively imprinted, whereas flexible compounds with two aromatic rings connected by polymethylene chain do not exhibit imprinting effect. Imprinting effect of these guest molecules can be attributed to inclusion complexation, not to hydrogen bonding. Tailor-made receptors of CD-MIPs have been studied extensively [66] and are reviewed [67]. The CD-MIPs are prepared in DMSO and cannot be used for molecules having carboxylate or amino groups. Molecular imprinting is successfully carried out in bulk water by use of the vinyl monomer of CD (Fig. (2A)) [68]. This method is advantageous for the templates which are large enough and sparingly soluble in water. Between the two imprinting methods in Fig. (2), an appropriate one can be selected depending on the purpose and the target molecule. Sometimes, 6-O- α -D-glucosyl- β -CD (G1- β -CD) is used instead of β -CD in order to improve the solubility in water and facilitate the column chromatography [58].

There are some other CD-MIPs applied to separate cholesterol [69]. Zhong et al. uses cholesteryl acrylate (CA) and acryloyl-6amino-6-deoxy- β (or γ)-cyclodextrin as monomers to prepare MIP [70]. Separation can be achieved in the solvents containing water since binding of guest molecules is based on inclusion complexation with CDs. Usually, MIPs ground with mortar and pestle are irregular in size and shape, thus they cannot be applied in pharmaceutical field. Instead, the uniformed molecularly imprinted microspheres (MIMs) by cyclodextrin have been prepared in a DMSO/poly(dimethylsiloxane) (PDMS) emulsion using cholesterol as the template [71]. Herein, PDMS is a suitable dispersing medium for the preparation of MIMs and the size of MIMs can also be changed by the viscosity of PDMS. Temperature also influences the MIMs. MIMs prepared at 65 °C are in an aggregated form, while uniform MIMs are obtained at 95 °C. The binding sites exist both on the surface of MIMs and within them. Similar to conventional MIPs, CD-MIPs can also be synthesized by the photochemical approach [72]. β-CD is not only a host molecule for cholesterol, but also a carrier of photoactive functionalities. A polymeric material which is obtained by crosslinking of β-CD substituted with cinnamoyl chromophores can be used as a matrix for photochemical reversible molecular imprinting. The condition is mild and provides a better kinetic control over imprinting process compared with conventional imprinting technology.

In order to understand the mechanism for recognition directly, the processes of MIP based on β-CD with cholesterol and stigmasterol (cross-linking agent: TDI and HMDI) are studied by matrixassisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF MS) and NMR spectroscopy [73]. Dimers and trimers of β -CD are formed only in the presence of templates, while the formation becomes inefficient in the absence of templates. These ordered assemblies contain two or three β-CD molecules, which cooperate to bind large steroids. When β-CD is replaced with 2,6-di-O-methyl-\beta-cyclodextrin (2,6-DM-\beta-CD), ordered assemblies are also formed, which indicates the significant roles of the secondary OHs in the molecularly imprinting of β -CD. The proposed mechanism is as follows (Fig. (3)). First, one of the two isocyanate groups of cross-linking agent reacts with β-CD, which mainly occurs at the primary OH groups (either with the template or without it). When the other isocyanate groups react with β -CD under imprinting conditions, the reaction preferentially takes place at the secondary OH. Importantly, the cholesterol penetrates into the

Fig. (4). Schematic illustration of the binding of D-phenylalanine in an imprinted polymer composed of polymerizable β -CD, 2-acryloylamido-2,2',dimethylpropane sulfonic acid (AMPSA), and *N*,*N*',diacryloylpiperazine. Taken from Ref. [74].

cavity of the second β -CD from its secondary hydroxyl side, rather than from the primary hydroxyl side.

Compared with CD-MIPs in DMSO, imprinting in water is much more important. However, MIP prepared in aqueous medium is difficult because water generally destroys the polar interaction between the functional monomer and the template molecule. The hydrogen bonding between CDs and analytes will be also destroyed by the addition of water. As a result, if the hydrophobic effect is the main interaction, imprinting can be realized in aqueous medium. The first rational use of the hydrophobic effect in conjunction with molecular imprinting in aqueous solution is reported for D- and Lphenylalanine, where bisacryloyl β-CD and 2-acryloylamido-2,2'dimethylpropane sulfonic acid (AMPSA) are functional monomers [74,75]. The imprinting effect is strong enough to reverse the inherent chiral selectivity of CD molecule for the L-form. This contributes to the combination of binding of the template phenyl moiety into the hydrophobic cavity of the CD, ion pairing and hydrogen bonding (Fig. (4)). The recognition utilizes a combination of the entropy-driven hydrophobic effect and enthalpy-motivated electrostatic interactions. Similar studies are reported for selective adsorption of norfloxacin [76] and enantioselective recognition of phenylalanine in aqueous media [77].

Many other molecules can be separated by CD-MIPs in aqueous medium. MIPs for 4,4'-(1,4-phenylenediisopropylidene)bisphenol (BPP) are prepared by bulk imprinting where β -CD is the functional monomer. The obtained MIPs can bind the template selectively in aqueous medium [78]. By the capping method of hydroxyl groups on β -CD molecule, the fact that hydrophobic effects play an important role in the recognition process is discovered.

CD-MIPs can recognize oligopeptides, antibiotics and so on. Creatinine-imprinted poly (β -CD) is synthesized for the specific binding of creatinine [79,80]. As creatinine molecule is hydrophilic, it has less chance to enter the hydrophobic central core of β -CD. By comparing the binding effect of MIP and chlorotrimethylsilane (CTMS)-capped MIP, it is found that hydrogen bonding and stereo-shape effects are important factors for the efficient binding of creatinine.

MIP using β -CD as functional monomer recognizes bilirubin (BR) specifically and reversibly [81]. The specificity may be due to the cooperative effects of inclusion complexation and hydrogen bonding between BR and β -CD. For the BR-imprinted polymer, a self-assembled process between β -CD and BR exists prior to polymerization. β -CDs are arranged in order in the presence of BR. Then, following the polymerization and subsequent removal of BR, this kind of orderly arrangement is reserved. And the formed cavities that are complementary in size and shape to BR are capable of recognizing BR with a high specificity. Whereas, for the non-imprinted polymer, due to the absence of a self-assembled process prior to polymerization, β -CDs are organized randomly. Therefore, the formed β -CD cavity arrangement in the non-imprinted polymer has no size-fit effects with BR. This interpretation is in accordance with the report before [73].

CD-MIPs can be applied in other fields, such as protein refolding [82], that is, molecularly imprinted poly (β -CD) polymer strips detergent molecules from the detergent-protein complexes and results in successful protein refolding processes. Also, CD-MIPs can be used to improve adsorption capacity [62] and as an adsorbent matrices applied in chromatography, especially as stationary phases of high performance liquid chromatography (HPLC) [65,69,70,83].

2.2. Surface Imprinting

Surface imprinting, or surface molecular imprinting technology is a method which generates cavities on the surface or close to the surface of materials facilitating the mass transfer of template [84]. The solid support can be silica-gel, alumina and polymers [83]. Fig. (5) demonstrates the process of CD-MIPs on the surface of silicagel, which is one of the most effective methods for the immobilization of imprinted polymers [85].

Conventionally, the redox initiator is directly added to the mixture of the β -CD-template complex, crosslinker, and surfacemodified silica-gel. A new polymerization process is developed [85]. Firstly, the redox initiator is mixed with the surface-modified silica-gel. Then, vinylated β -CD, crosslinker, and the template are added. This modification promotes the immobilization of β -CD copolymer to the silica-gel, resulting in still lower pump pressure when it is used as stationary phase of HPLC. Consequently, the imprinting efficiency is increased. A thin layer of CD-MIPs on a porous silica-gel support is prepared for the recognition of L-Phe-L-Phe and D-Phe-D-Phe [83]. By this method, CD-MIPs can be stiff enough for the stationary phase for HPLC.

On the surface of different solid supports, *i.e.*, modified silicagels, alumina and poly (hydroxyethyl methacaylate) (Poly-HEMA) (Fig. (6)), the MIPs recognizing tripeptide H-Phe-Lys-Phe-NH₂ have been compared [86]. All the imprinted β -CD polymers show notable imprinting effects, though there are differences in the surface charges and other physicochemical properties of these solid

Fig. (5). Procedure of the immobilization of imprinted β -CD polymer on silica-gel. Taken from Ref. [85].

Fig. (6). Preparation of various supports bearing vinyl groups for the β -CD molecular imprinting. Taken from Ref. [86].

supports. This report validates that ordered assembly of β -CD is the origin of molecular imprinting.

The position of vinyl group on β -CD influences the imprinting effect greatly because it governs the distance between the template and polymerization site. Two kinds of vinyl monomers of β -CD, mono-3-(*N*-acrylamido)-3-deoxy-altro- β -cyclodextrin (3-AAm-CD) and mono-6-(*N*-acrylamido)-6-deoxy- β -cyclodextrin (6-AAm-CD or 6-AAm- β -CD), which tether a vinyl group on either wider rim of the truncated cone or its smaller rim, are synthesized [87]. The imprinting effects of 3-AAm-CD and 6-AAm-CD toward *N*-benzyloxycarbonyltyrosine (Z-Tyr) in water by surface imprinting technology are compared. 3-AAm-CD shows a remarkable imprint

ing effect for the enantioselective recognition of Z-Tyr, while 6-AAm-CD hardly exhibits enantioselectivity. By NOESY analysis on the preorganized β-CD/Z-Tyr complex in D₂O, the two aromatic rings are found to enter the β-CD cavities from the secondary OH side. As a result, in the case of 3-AAm-CD, the vinyl groups protrude toward the template molecule. When a radical initiator is added to the mixture of this preorganized complex and crosslinking agent, copolymerization proceeds around the template molecule. Accordingly, the shape of template molecule can be precisely copied on the cross-linked polymer (Fig. (7A)). For 6-AAm-CD, the vinyl group is located in the primary OH side and protrudes toward the opposite side of the template. In this case, copolymerization occurs far from the template molecule so that only the positions of β -CD are regulated and some vacant space is formed around the template (Fig. (7B)). Consequently, the shape of template molecule is only coarsely copied to the polymer.

However, MIPs made from 6-AAm-CD are efficient for larger oligopeptide, such as the angiotensin \parallel (Asp-Arg-Val-Tyl-Ile-His-Pro-Phe) and so on (as shown in Fig. (8)) [57]. The imprinted β -CD polymers memorize peptide conformations rather than their primary structures alone.

Cholesterol can also be separated by surface imprinting. For example, MIP of β -CD/cholesterol template is prepared on a tetraethoxysilane (TEOS) silica polymer by sol-gel technique [88]. They create hydrophobic solid matrices that can recognize and bind biologically significant molecules.

Among different β -CD monomers, acryloyl β -CD offers hydrophilic exterior and hydrophobic cavity and thus is used frequently. For the first time, acryloyl β -CD together with the acrylamide (AA) is used for protein imprinting by surface modified MIP [89]. Silicagel is replaced by silica beads and the spherical beads are preferred over irregular particles. The template protein, lysozyme (Lyz) is covalently immobilized on the surface of silica beads (Fig. (9)). Interactions between β -CD and protein involve the hydrogen bonding and hydrophobic interaction by adsorption studies. When the template is removed, complementary binding sites are created on the surface of silica beads. The imprinted polymer can recognize template protein from mixtures.

Fig. (8). Schematic view of molecular imprinting of β -CD toward oligopeptide template. Taken from Ref. [57].

A novel MIP prepared with vinyl-bonded β -CD and AA by surface molecular imprinting technique on functionalized silica gel can selectively recognize tryptophan (Trp) in aqueous medium [90]. This method is different from reports using acryloyl β -CD [74,87]. It provides more effective recognition sites than the polymer of acryloyl β -CD, which is just simply random grafted on the matrix. By HPLC column packed with this MIP, it can separate not only Trp from other aromatic amino acids, but also the template from its enantiomer in aqueous mobile phase. However, the absence of AA cannot reverse the inherent selectivity of the β -CD moiety for the L-form. The good property is mainly attributed to the combination interactions of hydrophobic effect between bonded β -CD and Trp and hydrogen bond between AA and Trp. It is a promising method for chiral amino acid separation and purification.

A new surface imprinting technique is applied to synthesize uniformly sized MIMs using ursolic acid (UA) as the template [91]. Uniformly sized functionalized poly (glycidyl methacrylate) microspheres (F-P_{GMA}) are used as the support matrix. As shown in Fig. (10), bonded β -CD and AA can form complex with UA through the hydrophobic interaction and the hydrogen bonding simultaneously, which is in good agreement with the two-site binding model. As a result, MIMs can separate UA from herbs effectively. This method provides a new way of preparing uniformly sized spherical imprinted polymers with β -CD as functional monomer. This method is also used in solid-phase extraction and it is the first time for the molecularly imprinted solid-phase extraction (MISPE) to be applied to the extraction of UA from herb [92].

3. COOPERATI VE EFFECTS OF CYCLODEXTR INS AN D IONIC LIQUIDS IN SEPARATION PROCESSES

CDs and ILs are used together mainly in the separation methods of capillary electrophoresis (CE) and gas chromatography (GC). In the processes, the interaction of ILs, CDs and analytes is important. ILs and CDs demonstrate cooperative effects for separation of analyte. Typical cations and anions of ILs are shown in Fig. (11).

3.1. Capillary Electrophoresis

CE is one of the most important methods in separation science. CDs are now widely used as run buffer additives for CE analyses and have been reviewed [93,94]. It has been shown that the selectivity of CE is enhanced by using CDs as chiral selectors due to their ability to include a wide variety of water-insoluble molecules into their hydrophobic cavity. ILs are also applied in CE extensively [95,96]. In general, the presence of ILs in running electrolytes make the ions coat the capillary walls thus engendering anodic electroosmotic flow (EOF).

ILs can be separated by CDs. The separation of 1-alkyl-3methylimidazolium, including isomers and related imidazole derivatives is performed by α -cyclodextrin (α -CD) modified capillary zone electrophoresis [97]. This is the first report on separation of dialkylimidazolium and related imidazoles by CE, due to different interactions of ILs and α -CD. For example, the migration time of 1butyl-3-methylimidazolium (C₄mim) increases more significantly than those of other ILs on the addition of α -CD. As for 1-iso-butyl-

Fig. (9). The protocol for synthesis of the protein imprinted polymer. Taken from Ref. [89].

Fig. (10). Scheme for MIMs (UA as the template). Taken from Ref. [91].

3-methylimidazolium (i- C_4 mim), the methyl group on the isobutyl makes it not favor entering the α -CD cavity. Instead, C_4 mim enters the cavity. This method can be employed to detect impurities in commercial chemicals because most of ILs originates from 1-alkyllimidazolium. Also, the method can be applied in process analysis during synthesis of ILs and provide information on the reaction mechanism.

When ILs are used as background electrolyte (BGE) and covalent coating reagent for determination of metal ions, CDs can be added to improve the properties and effects [98]. With the addition of α -CD into run buffer, the mobility of C₆mim⁺ can be modified.

The influence of α -CD on the detection sensitivity of ions is demonstrated in Fig. (12). Though the peak height ratio increases significantly with the concentration of α -CD lower than 12mM, introduction of α -CD does not bring obvious influence on the mobilities or migration order of the metal ions. This may be because the complexing ability of α -CD to 18-crown-6 or metal ion is very weak. As a result, we can choose proper concentration of α -CD to realize the separation.

Chiral ILs as additives to CDs for enantiomeric separations are evaluated by CE [23,24,99]. These chiral ILs (ethyl- and phenylcholine (EtChol and PhChol), of bis(trifluoromethylsulfonyl)imide)

alone cannot present any enantioselectivity with regard to model analytes, 2-arylpropionic acids. The influence of the ILs is studied in aqueous and hydro-organic electrolytes containing CD selectors (dimethyl- β -cyclodextrin, DM- β -CD or trimethyl- β -cyclodextrin, TM- β -CD). Because of the synergistic effects, a possible competition between the analyte and the IL cation for inclusion complexation with CD (Fig. (13)), an increase in separation selectivity and resolution is observed in some cases. This is maybe because of the specific ion-pairing interactions of anionic profen A⁻ and IL⁺, since there is no inclusion between EtChol cation and the two β -CD derivatives. For PhChol, there is no inclusion of PhChol cation into TM- β -CD cavity. However, it forms a complex with DM- β -CD due to more important steric hindrance of TM- β -CD as compared with DM- β -CD. The kind of CD can influence the competitive complexation of analyte or IL with CD.

Similar studies are applied to enantioseparate β -agonists using β -CD as the chiral selector and tetraalkylamminium-based ILs (tetrabutylammonium hydroxide (TBAOH) and tetramethylammonium hydroxide (TMAOH)), alkylimidazolium-based ILs ([C₄mim][BF₄], [C₄mim][PF₆]), alkylpyridinium-based ILs ([C₄Py][PF₆], [C₈Py][PF₆] and [C₄Py][BF₄]) as the modifiers [100]. These ILs are examined and compared for controlling the EOF in order to improve resolution capacity of β -agonists enantiomers. And the ILs influence the elution time, elution order and peak efficiency of enantiomers. There is also the competition of CD

Fig. (13). Schematic description of the interaction system between anionic profen A^- , chiral IL⁺ cation, free in the BGE or adsorbed onto the capillary wall, and β -CD derivatives. Taken from Ref. [24].

time of $[C_4Py][PF_6]$ (Fig. (14)). The process may be conducted by hydrophobic, hydrogen bonding or ion-dipole/ion-induced-dipole interactions. The long chain of $[C_8Py][PF_6]$ enters the cavity of β -CD, which competes with β -agonists enantiomers and results in poor chiral resolutions.

 $[C_4 mim][BF_4]$ and β -CD can be used in CE for the determination of anthraquinones in Chinese herb [25]. When there is no β -CD, analytes are only partially separated. After adding β -CD of proper concentration into the running buffer, clear separation of real sample can be achieved. The mechanism of the separation of anthraquinones is shown in Fig. (15). Anthraquinones can associate

Fig. (14). Mechanism of enantioseparation of β -agonists enantiomers using [C₄Py][PF₆] with β -CD. Taken from Ref. [100].

Fig. (15). Mechanism of the separation of anthraquinones using C_4 mim⁺ based ionic liquid and β -CD. Taken from Ref. [25].

inclusion complexation between β -agonists and ILs. TMAOH is the smallest one with the least tendency to be included in the cavity of β -CD, thus it is less competitive for the enantioselective sites of β -CD. There are many factors attributed to the length of the migration

Fig. (16). Two-Step Equilibrium in an IL/ β -CD System (Path I: the cation interacts with β -CD more strongly than the anion does.) Path II: the anion interacts with β -CD more strongly than the cation does.). Taken from Ref. [115].

with the imidazolium ions or β -CD, respectively. In the presence of β -CD coexisting with IL, anthraquinones may be entirely or partly embedded the cavity of β-CD and the association of anthraquinones with free imidazolium ions is weaken. This association is partially driven by the hydrophobic, hydrogen bonding, or by the iondipole/ion-induced-dipole interactions between the anthraquinones and $[C_4 mim][BF_4]$. And those analytes, which are not embedded the cavity of β-CD have rather stronger association with the imidazolium ions in the system. Therefore, the association between the analytes and the imidazolium ions is different. Consequently, this different association or embedding makes the mixture of anthraquinones to be separated excellently. Similar studies are used to simultaneous determination of bioactive flavone derivatives in Chinese herb [101]. [C₄mim][BF₄] and [C₂mim][BF₄] are appropriate to be used as running electrolytes in CE, especially in high ionic strength.

The use of IL and CD in CE can also be applied to investigate the complexation between IL and CD. Affinity capillary electrophoresis (ACE) method is developed to quantitatively characterize the complexation between alkyl (methyl) methylimidazolium-based IL cations and neutral CDs in water [102]. ACE is based on the alteration of analyte effective mobility due to in situ complexation in ligand-containing electrolytes. The absolute mobilities of the free and bound forms of the analyte are different, then a shift in the position of the analyte peak is expected as the ligand concentration in the running buffer varies. Upon increasing β -CD concentration, an increase in the migration time of the IL cation is observed, indicating the formation of a complex between these species. Thus, by classical nonlinear and linear treatment, the complex stoichiometry and formation constant K are obtained. This method can keep the consumption of analytes and ligand to a minimum. It realizes the online detection, short analysis times and should be of interest for liquid chromatography (LC) and CE.

Beside the application in CE, $[C_2mim][BF_4]$ as the working electrolyte is used in chiral separation for dipeptides in glass microchip electrophoresis [103]. In this report, different CDs are selected for chiral separation of Gly-D,L-Phe. β -CD and negtively charged carboxy-methyl- β -CD (CM- β -CD) cannot perform the chiral separation when $[C_2mim][BF_4]$ is the working electrolyte. For CM- β -CD, the migration times of analytes are delayed. It is the result of the direction of CM- β -CD inclined to the anode while the analytes are driven toward the cathode by EOF in basic buffer, and more probabilities exist for analytes to touch with selector. It is suggested that outer groups of CD cavity in IL solution are related to the chiral separation.

3.2. Gas Chromatography

As early as 1999, the idea that ILs can be used as stationary phases for GC was promoted [104]. There are many reviews about the application [105,106]. Maybe it is because their wetting ability and viscosity allow them to be coated onto fused silica capillaries. It is pointed out that ILs can solubilize complex macrocyclic molecules such as CDs and their derivatives and so on [107]. As a result, ILs are helpful in separation methods of CDs. Though there are a number of MIPs of cyclodextrins applied into GC, the direct incorporation of ILs and CDs is scarce. The only report is that $[C_4mim][PF_6]$ as stationary phase solvents for methylated cyclodextrins in GC [108]. The results show that compared with commercial columns containing the same chiral selectors with the IL containing columns, the IL containing columns are worse. It is suggested that the C_4mim^+ can form an inclusion complex with the CD cavity, blocking it for chiral recognition.

When both CDs and ILs are used in separation processes, the interaction between them becomes important and inevitable. Different methods have been applied to investigate the interaction of CDs and ILs [109-111], *e.g.*, solubility [112], FT-IR spectra [113], Powder X-ray diffraction (XRD) [112-114], conductivity measurement [115,116], TGA [112-114], ACE [102], NMR [113-116], competitive fluorescence method [115,117], microcalorimetry [116,118], surface tension measurement [114].

Though there are some researches on the interaction of CDs and ILs, the controversy about the segment of ILs entering the cavity of CDs and the factor influencing the interaction pattern exists [113,114]. Considering the studies on complexation of ILs and CDs, the general pattern in an IL/ β -CD system and a two-step equilibrium is brought forward as shown in Fig. (16) [115]. It is confirmed that the alkyl side chain on the imidazolium ring but not the imidazolium ring itself enters the cavity of β -CD. As for the IL [C₁₂mim][Tf₂N], the cation and the anion exhibit strong interactions with β -CD simultaneously. The strength of the interaction of vari-

ous cations and anions in ILs with β -CD follows the following order: NfO⁻ > C₁₂mim⁺ > Tf₂N⁻ ~ AdCO₂⁻ ~ C₁₀mim⁺ > C₈mim⁺ > 1hexyl-2,3-dimethylimidazolium cation (C₆dmim⁺) ~ PF₆⁻ > BF₄⁻ > 1-butyl-2,3-dimethylimidazolium cation (C₄dmim⁺) ~ C₄vim⁺ ~ C₄mim⁺ > Cl⁻. Besides, because inclusion complexes of CDs and ILs can influence the binding constants of guest and CDs [119,120], the rules of the general interaction pattern between ILs and β -CD can be considered to improve separation process, control the supramolecular organizations and so on.

4. CONCLUDING REMARKS

CD-MIPs have been applied for separation of small molecules, nanometer-scaled molecules and larger bioactive molecules in nonaqueous and aqueous media. The imprinting can be realized mainly due to the formation of CD ordered assemblies. Generally, between two technologies of preparing CD-MIPs, *i.e.* bulk imprinting and surface imprinting, the latter one is superior in the properties of MIPs, especially in aqueous media. However, there are also many obstacles to overcome. How to realize the separation accurately, quickly, enormously and environment friendly is a topic to be further studied. Thus, the conditions of preparation must be mild, the medium must be non-toxic, and the reactants must be recyclable. Generally, CD-MIPs are used for molecules and rarely for ions. It should be possible for ionic imprinted polymers consisting of cyclodextrins to be used in separation of ions. In the future, more researches will be possibly focused on these topics.

ILs and CDs together are being studied to apply into separation methods, *e.g.*, CE, GC and so on. When CDs are running electrolytes of CE, the addition of ILs can take synergic or reverse effects on the separation processes. Similarly, if ILs are used as BGE, CDs can be applied to improve the effects of separation. These separation methods can be applied to determine association constants of ILs and CDs. Considering the general pattern of interaction between ILs and CDs, the separation can be better controlled. If the substituted cyclodextrins were prepared into a new type of ILs, the merits of CDs and ILs can be united together and these new ILs will be applied more extensively.
